Opioid prescribing practices for at-risk pediatric populations undergoing ambulatory surgery

INTRODUCTION

- At-risk populations for post-surgical opioid-induced respiratory depression include pediatric patients with a history of sleep-disordered breathing (SDB) or obstructive sleep apnea (OSA).
- Monitoring in the inpatient setting allows for increased vigilance for opioid-related adverse events, children with the aforementioned comorbidities are presumably at even greater risk when undergoing outpatient surgical procedures since there is far less monitoring in place for recognition of events.
- We aim to describe our current opioid prescribing practices for outpatient surgical procedures in order to determine whether providers modify prescriptions for certain patient comorbidities, weight or BMI-for-age percentiles.
- By shedding light on our current practices, we intend to create an evidence-based framework to institute standardized dosing for this group.

METHODS

- Baseline opioid prescribing data for all outpatient pediatric surgical patients (ages 0-18) were collected and retrospectively from January 1, 2015 to May 31, 2019 and reviewed.
- Those with an ICD-10 code for sleep-disordered breathing or OSA (J53.5, J53.2, G47.3, G47.33), obesity (E66.6) or those who were considered obese based on BMI-for-age percentile (268.54) were identified.
- Patients were included if they were discharged with an opioid prescription or with current procedural terminology (CPT) codes reflective of surgical interventions likely to produce an opioid prescription.
- Data retrieved from the electronic medical record used at Children's Hospital Colorado (Epic) included:
  - Patient demographics (age, race, BMI-for-age percentile at time of surgery, ideal body weight, ASAH physical status)
  - Opioid prescription descriptors (dose, frequency and duration of prescription)
  - Surgical specialty/service (including specific procedure type based off of CPT codes or chart review).
- We also noted if an opioid prescription refill was required, and if patients re-presented to the emergency department or were readmitted for pain.

Statistical Analysis

- Study data were collected and managed in an encrypted file with all patient identifiers removed.
- Patient demographics were summarized using descriptive statistics; counts and percentages were used for class/categorical variables, while medians and ranges were used for continuous variables given their non-normal distributions.
- We compared characteristics for the obese group and SDB/OSA group to the control group, respectively. We then compared characteristics between the low and standard dose cohorts within the obese and SDB/OSA groups, respectively.
- Wilcoxon rank sum tests were applied to compare the distributions of continuous variables, while Pearson's chi-square or Fisher's exact tests were used to evaluate differences in proportions of the class/categorical variables between groups. P-values < 0.05 were considered statistically significant. SAS V9.4 was used to conduct all the data analyses.

RESULTS

- Data was collected on 4674 patients
- 173 patients were identified with OSA/SDB, or tonsillar and/or adenoid hypertrophy
- 128 patients were defined as obese (BMI > 95%) (Table 1)

CONCLUSIONS

- More than half of clinicians (61%) prescribed opioids based on actual body weight independent of dose for SDB and obese patients.
- However, most were prescribed at a reduced dose indicating they were aware of the increased risk for opioid complications (<0.05mg/kg, n=155, 84.2%).
- When actual body weight was used, providers most likely reduced the dose of oxycodone (<0.05mg/kg, n=155, 84.2%).
- When ideal body weight was used, we observed a trend in which most prescriptions were written using the standard dose of oxycodone (<0.05mg/kg).
- While the risk of overdose in obese and SDB patients is less likely when using IBW over AWB, the reduction in dose infers that providers were at least aware of this potential for these issues.
- This also suggests that practitioners were more inclined to estimate proper doses rather than undertake lean body mass calculations.
- Inconsistency surrounding proper dosing in these patients are further highlighted with thirty SDB patients who underwent surgical procedures typically warranting an opioid analgesic but did not receive an opioid prescription at discharge.
- Furthermore, while our institution does not commonly prescribe opioids to children under the age of 5 undergoing tonsillectomy/adenoidectomy, seven children in that age range received an opioid for these procedures.
- These prescribing practices confirm that there is high variability in dosing between providers for similar procedures.
- Why isn't ideal body weight being used?
- More complex calculations are involved compared to ideal body weight
- Some providers are unaware of dose change suggestions
- Future work: identify knowledge gaps in appropriate opioid prescribing and factors for lack of adherence to proper dosing in these at-risk populations
